Zero- and longitudinal-field muon spin relaxation experiments have been carried out in the alloy series $\text{Pr}(\text{Os, Ru})_4\text{Sb}_{12}$ and $\text{Pr}_1-\text{yLa}_y\text{Os}_4\text{Sb}_{12}$ to elucidate the anomalous dynamic muon spin relaxation observed in these materials. The damping rate $\Lambda$ associated with this relaxation varies with temperature, applied magnetic field, and dopant concentrations $x$ and $y$ in a manner consistent with the “hyperfine enhancement” of $^{141}\text{Pr}$ nuclear spins first discussed by Bleaney [Physica (Utrecht) 69, 317 (1973)]. This mechanism arises from Van Vleck-like admixture of magnetic $\text{Pr}^{3+}$ crystalline-electric-field-split excited states into the nonmagnetic singlet ground state by the nuclear hyperfine coupling, thereby increasing the strengths of spin-spin interactions between $^{141}\text{Pr}$ and muon spins and within the $^{141}\text{Pr}$ spin system. We find qualitative agreement with this scenario and conclude that electronic spin fluctuations are not directly involved in the dynamic muon spin relaxation.

I. INTRODUCTION

The filled-skutterudite compound $\text{PrOs}_4\text{Sb}_{12}$ is the first praseodymium-based heavy-fermion superconductor to be discovered and is one of the few $f$-electron heavy-fermion compounds in which a non-Kramers ion exhibits a nonmagnetic crystalline-electric-field (CEF)-split ground state. Both the normal and superconducting states of $\text{PrOs}_4\text{Sb}_{12}$ are unusual: The $\Gamma_1$ singlet $\text{Pr}^{3+}$ ground state is separated from a $\Gamma_4$ first excited state (tetrahedral notation) by a remarkably small splitting $\Delta E_{\text{CEF}}/k_B \approx 7$ K, leading to strong CEF effects at low temperatures. There is no sign of magnetic ordering. The Sommerfeld coefficient $\gamma$ is difficult to measure in the presence of the CEF Schottky anomaly in the low-temperature specific heat but is estimated to lie between 500 and 750 mJ mol$^{-1}$ K$^{-2}$. The $\text{Pr}^{3+}$ ions are enclosed in an icosahedral cage of Sb atoms that is considerably larger than the ionic size, and large-amplitude Einstein-like $4f$-ion phonon modes (“rattling” modes) are observed. Below the superconducting transition temperature $T_c = 1.85$ K, an unconventional superconducting phase is found, with evidence for multiple phases, time-reversal symmetry breaking, and extreme multiband behavior. Dispersive antiferroquadrupolar excitons and an unusual low-temperature high-field phase with antiferroquadrupolar order are observed. The mechanism or mechanisms for heavy-fermion behavior and Cooper pairing in this compound remain controversial; rattling
modes\textsuperscript{11} and Pr\textsuperscript{3+} quadrupole fluctuations\textsuperscript{12} have been proposed.

Muon spin relaxation ($\mu$SR),\textsuperscript{13,14} like other magnetic resonance techniques, probes magnetism and electronic structure in solids on the microscopic (atomic) size scale. In $\mu$SR experiments, spin-polarized positive muons ($\mu^+$) are implanted into the material of interest and stop at interstitial sites. During its lifetime, each muon precesses in the magnetic field at its site and eventually decays ($\mu^+ \rightarrow e^- + \nu_e + \bar{\nu}_\mu$); the direction of the emitted positron’s momentum is correlated with the muon spin direction at the moment of decay. A large number of such events determine the time development (relaxation) of the ensemble-average muon spin polarization. Several $\mu$SR studies of Pr-based filled skutterudites have been reported.\textsuperscript{8,15–20}

The magnetic environment of the muon creates a local field $H_{\text{loc}}$ at the muon site that causes muon spin relaxation. Relaxation mechanisms can be divided into two classes, depending on the behavior of $H_{\text{loc}}$, as follows:

(a) Static (or quasistatic\textsuperscript{21}) relaxation is due to an inhomogeneous static distribution of $H_{\text{loc}}$ that causes a spread of muon Larmor frequencies and consequent loss of muon spin phase coherence.

(b) Dynamic relaxation (often called spin-lattice relaxation in the NMR literature) is due to thermal fluctuations of $H_{\text{loc}}$ that induce transitions between muon spin levels and equilibrate the muon spin populations. The equilibrium muon spin polarization is negligible compared to the initial polarization ($\sim 100\%$). The dynamic component of $H_{\text{loc}}$ usually arises from electronic spin fluctuations; we shall see, however, that nuclear spin fluctuations can also be involved.

In longitudinal-field $\mu$SR (LF-$\mu$SR), which includes zero-field $\mu$SR (ZF-$\mu$SR) as a special case, a magnetic field $H_L$ is applied parallel to the initial muon spin polarization. The dependence of the muon spin relaxation on $H_L$ helps us to separate the static and dynamic contributions to the relaxation.\textsuperscript{22,23}

The ZF-$\mu$SR spin relaxation function in PrOs\textsubscript{4}Sb\textsubscript{12} at low temperatures\textsuperscript{8} could be fitted by the product of an exponential damping factor $\exp(-\Delta t)$ and the Kubo-Toyabe (KT) functional form\textsuperscript{22,23} expected for a Gaussian quasistatic field distribution. This was attributed to a two-component form of $H_{\text{loc}}$: a static component responsible for the KT relaxation and a second component responsible for the exponential damping, which was determined by LF-$\mu$SR measurements to be due to dynamic fluctuations.\textsuperscript{8} The origin of this dynamic component was not clear, although 4f-electron dynamics associated with the small CEF splitting was noted as a possible mechanism. In the normal state above $T_c$, the quasistatic field distribution was attributed to dipolar interactions between muon spins and neighboring (principally $^{121}$Sb and $^{123}$Sb) nuclear magnetic moments. An increase in the quasistatic relaxation rate was observed below $T_c$ and interpreted as evidence for time-reversal symmetry breaking in the superconducting state of PrOs\textsubscript{4}Sb\textsubscript{12}.\textsuperscript{8} This effect has also been studied in Pr(Os\subscript{1−δ}Ru\subscript{δ})\textsubscript{4}Sb\textsubscript{12} and Pr\subscript{1−y}La\textsubscript{y}Os\textsubscript{4}Sb\textsubscript{12} alloys,\textsuperscript{24,25} which are superconducting for all $x$ and $y$ with $T_c$ of the order of 1 K.\textsuperscript{26,27}

In this paper, we report results of ZF- and LF-$\mu$SR experiments in the Pr(Os\subscript{1−δ}Ru\subscript{δ})\textsubscript{4}Sb\textsubscript{12} and Pr\subscript{1−y}La\textsubscript{y}Os\textsubscript{4}Sb\textsubscript{12} alloys.\textsuperscript{28} which have been undertaken to elucidate the anomalous exponential damping. We confirm that the damping is indeed dynamic in nature and argue that it is due to enhancement of $^{141}$Pr nuclear magnetism via intra-atomic hyperfine coupling to the Pr\textsuperscript{3+} 4f electrons.\textsuperscript{29} This coupling induces a Van Vleck-like admixture of low-lying Pr\textsuperscript{3+} magnetic CEF-split excited states into the singlet ground state, thereby increasing the effective $^{141}$Pr nuclear moment. Both the $^{141}$Pr-$\mu^+$ and the $^{141}$Pr-$^{141}$Pr dipolar interactions are increased (by factors of $\sim 20$ and $\sim 400$, respectively) by this “hyperfine-enhancement” mechanism, which also increases indirect $^{141}$Pr-$^{141}$Pr interactions mediated by exchange coupling between Pr\textsuperscript{3+} ions.\textsuperscript{29} Hyperfine-enhanced $^{141}$Pr nuclear moments have a significant effect on muon spin relaxation; the mechanism accounts for the observed damping of the muon spin relaxation and is qualitatively consistent with the behavior of the damping rate $\Lambda$ with enhancement strength and Pr-ion concentration dependence (for Pr\subscript{1−y}La\textsubscript{y}Os\textsubscript{4}Sb\textsubscript{12} alloys) across both alloy series. Exchange-mediated interactions appear to dominate the $^{141}$Pr spin dynamics. The origin of the dynamical muon spin relaxation has been clarified, and we conclude that electronic spin fluctuations (except those associated with the hyperfine-enhancement mechanism) are not directly involved in the anomalous muon spin relaxation.

The paper is organized as follows. After a brief description of the experiments in Sec. II, we report our experimental results for Pr(Os\subscript{1−δ}Ru\subscript{δ})\textsubscript{4}Sb\textsubscript{12} and Pr\subscript{1−y}La\textsubscript{y}Os\textsubscript{4}Sb\textsubscript{12} in Sec. III. We consider the dependence of the muon exponential damping rate $\Lambda$ on $H_L$, temperature, and dopant concentrations $x$ and $y$ and their implications for the mechanism for the dynamic muon spin relaxation in Sec. IV. Our conclusions are summarized in Sec. V.

II. EXPERIMENTS

ZF- and LF-$\mu$SR experiments were carried out in Pr(Os\subscript{1−δ}Ru\subscript{δ})\textsubscript{4}Sb\textsubscript{12}, $x=0.05$, 0.1, 0.2, 0.6, and 1.0, and (Pr\subscript{1−y}La\textsubscript{y})Os\textsubscript{4}Sb\textsubscript{12}, $y=0.2$, 0.4, 0.6, and 0.8. ZF- and LF-$\mu$SR experiments were carried out on powdered samples at the Meson Science Laboratory, KEK, Tsukuba, Japan, and the MuSR spectrometer at the ISIS neutron and muon facility, Rutherford Appleton Laboratory, Chilton, UK. LF-$\mu$SR experiments were carried out at the M15 beamline at TRIUMF, Vancouver, Canada, on mosaics of oriented $\sim 1$ mm\textsuperscript{3} crystals, prepared by the Sb-flux method,\textsuperscript{30} with $\langle 100 \rangle$ directions parallel to the applied field.

$^3$He–$^4$He dilution cryostats were used to obtain low temperatures. The mosaic crystals were mounted on a thin GaAs backing, which, at low temperatures, rapidly depolarizes muons and minimizes any spurious signal from muons that do not stop in the sample. Standard time-differential $\mu$SR asymmetry data\textsuperscript{13,14} were taken in the normal and superconducting states at temperatures in the neighborhood of $T_c$ for $H_L$ between 0 and 125 Oe.

III. EXPERIMENTAL RESULTS

A. Zero-field muon spin relaxation

Figure 1 shows the ZF-$\mu$SR positron count rate asymmetry\textsuperscript{13,14} $A(\Gamma(t))$, where $A$ is the initial asymmetry and...
$G(t)$ is the muon spin polarization (initially $\sim 100\%$), in Pr(Os$_{0.9}$Ru$_{0.1}$)$_4$Sb$_{12}$. The time-independent offset in Fig. 1 comes from nonrelaxing muons that stopped in the silver cold finger or elsewhere in the cryostat (i.e., did not stop in either the sample or the GaAs backing).

The zero-field static Gaussian KT relaxation function

$$G_{\text{KT}}^{0}(t, \Delta) = \frac{1}{3} + \frac{2}{3}(1 - \Delta^2 t^2)\exp\left(-\frac{1}{2} \Delta^2 t^2\right)$$

(1)

describes muon spin relaxation by randomly oriented quasi-static muon local fields, with Cartesian components that vary according to a Gaussian distribution with a zero mean value and an rms width $\Delta/\gamma_\mu$ ($\gamma_\mu$ is the muon gyromagnetic ratio). The “damped Gaussian KT” function

$$G(t) = \exp(-\Lambda t)G_{\text{KT}}^{0}(\Delta, t),$$

(2)

where $\Lambda$, the damping rate, was fitted to the experimental data (solid curve in Fig. 1). Although the data appear to decay roughly exponentially, it can be seen that the best fit to a simple exponential (dashed curve in Fig. 1) is not as good as the fit to Eq. (2).

Before further analyzing the relaxation data, we discuss the choice of Eq. (2) as a fitting function. In ZF- and LF-μSR, fluctuations of $H_{\text{loc}}$ are often treated using the “dynamic KT” relaxation function, in which $H_{\text{loc}}$ fluctuates as a whole with a single correlation time. Such a procedure is not appropriate in the present experiments, however. A quasi-static contribution to $H_{\text{loc}}$ due mainly to Sn nuclear dipolar fields, is also present, so that $H_{\text{loc}}$ is the sum of quasi-static and fluctuating components.

Figure 2 shows ZF-μSR data obtained from the isostructural compound LaOs$_4$Sb$_{12}$ (here, the time-independent signal has been subtracted), in which there are no 4f electrons. The best fit of Eq. (2) to these data yields a negligible exponential damping rate, indicating that the damping arises from the presence of Pr ions. The values of the KT relaxation rate in the normal state differ by only $\sim 15\%$ between PrOs$_4$Sb$_{12}$ [$\Delta = 0.143(5)$ $\mu s^{-1}$] and LaOs$_4$Sb$_{12}$ [$\Delta = 0.167(5)$ $\mu s^{-1}$]. In the latter compound, the nuclear dipolar field is the only mechanism for the static KT term.

This near equality is additional evidence that $\Delta$ is due to nuclear dipolar fields in PrOs$_4$Sb$_{12}$. Furthermore, significantly better fits to zero-field data are obtained using the damped static KT function (reduced $\chi^2$ typically $\sim 1.1$) than the dynamic KT function (reduced $\chi^2$ typically $\sim 1.4$). We therefore use damped static relaxation of the form of Eq. (2) to model the situation where muon spin states are split into Zeeman levels by the quasi-static component of $H_x + H_{\text{loc}}$, and the fluctuating component of $H_{\text{loc}}$ induces transitions between these Zeeman levels.

In Fig. 3, the damping rate $\Lambda$ in zero field for Pr(Os$_{1-x}$Ru$_x$)$_4$Sb$_{12}$, $x = 0.1, 0.2$, and $1.0$, is plotted vs temperature $T$ for $0.02 \leq T \leq 2$ K. As in PrOs$_4$Sb$_{12}$, little temperature dependence is observed in this temperature range; this is also the case for Pr$_{1-x}$La$_x$Os$_4$Sb$_{12}$ alloys (data not shown). This weak temperature dependence strongly suggests that $\Lambda$ is due to nuclear magnetism rather than electronic spin fluctuations: the latter would be expected to show significant temperature dependence, especially below $T_c$, whereas fluctuations arising from nuclear spin-spin interactions are temperature independent except at very low temperatures. The dynamic relaxation is unlikely to arise from fluctuations of $^{121}\text{Sb}$ and $^{123}\text{Sb}$ nuclear spins, which should result in quasi-static contributions to $H_{\text{loc}}$, because their

FIG. 2. Zero-field muon spin polarization decay function in LaOs$_4$Sb$_{12}$, $T = 0.91$ K. Data from Ref. 16. The signal from muons that do not stop in the sample has been subtracted. There is no significant exponential damping.

![Figure 3](image3.png)

FIG. 3. Zero-field exponential damping rate $\Lambda$ vs temperature in Pr(Os$_{1-x}$Ru$_x$)$_4$Sb$_{12}$, $x = 0.1, 0.2$, and $1.0$. The vertical lines indicate the superconducting transition temperatures for each alloy.
spin-spin and spin-lattice relaxation times are relatively long.\textsuperscript{33}

A candidate mechanism for dynamic muon spin relaxation is the hyperfine-enhanced \(^{141}\text{Pr}\) nuclear spin system with hyperfine-enhanced effective nuclear moments.\textsuperscript{26} Described briefly in Sec. I, which, as discussed below in Sec. III B, leads to dynamic muon spin relaxation rates in qualitative agreement with experiment. \(^{141}\text{Pr}\) nuclear spin fluctuations due to hyperfine-enhanced \(^{141}\text{Pr}-^{141}\text{Pr}\) spin-spin interactions can be rapid enough to cause dynamic muon spin relaxation, since both dipolar and exchange-mediated contributions to these interactions are increased by hyperfine enhancement. The observed nuclear Schottky anomaly in the low-temperature specific heat of \(\text{PrOs}_4\text{Sb}_{12}\) (Ref. 3) is similarly enhanced. Hyperfine-enhanced relaxation is independent of temperature for \(T < \Delta E_\text{CEF}/k_B\),\textsuperscript{34} which is roughly satisfied in the present experiments.

B. Longitudinal-field muon spin relaxation

We first review the effect of longitudinal applied field \(H_L\) on LF-\(\mu\)SR measurements.\textsuperscript{22,23} In the case where \(H_\text{loc}\) is quasistatic for \(H_L \gg 1/\gamma_\mu\), the (quasistatic) resultant field \(H_\text{res} + H_L\) is nearly parallel to the initial muon spin direction. Then, the precession that causes quasistatic relaxation is reduced in amplitude and the muon spin polarization is nearly time independent. For weaker fields \(H_L = \Delta/\gamma_\mu\), the muon polarization at long times increases with increasing \(H_L\). This phenomenon, called “decoupling,” does not occur for dynamic relaxation unless the latter is quenched for \(H_L \gg 1/\gamma_\mu\); this is unusual because nuclear dipolar fields are small, of the order of a few oersteds, and applied fields this small seldom affect dynamic relaxation mechanisms. Thus, LF-\(\mu\)SR measurements help us to determine whether the observed ZF relaxation is due to static or dynamic contributions to \(H_\text{loc}\).\textsuperscript{23} In favorable cases, the dependence of the damping rate \(\Lambda\) on \(H_L\) yields statistical properties (rms amplitude and correlation time) of the fluctuating field.\textsuperscript{23,35}

LF-\(\mu\)SR experiments were performed in weak longitudinal fields \(H_L\) in the normal state just above \(T_c\). Representative LF-\(\mu\)SR spectra are shown in Fig. 4. The data exhibit the late-time field dependence that is a characteristic feature of decoupling, together with overall damping that is stronger at lower fields. A “damped static longitudinal KT function” appropriate to nonzero \(H_L\), of the form of Eq. (2) with \(G_T(\Delta, t)\) the static Gaussian KT function in nonzero applied longitudinal field,\textsuperscript{23} was therefore fitted to the data. “Global” fits to all the field-dependent data at a given temperature were carried out, with \(\Delta\) taken to be independent of field but varied for best fit. The field dependence of \(\Lambda\) was obtained under this condition.

Figure 5 shows these field dependencies for several alloys. The fit values of \(\Delta\) are given in Table I, which also shows parameters derived from the field dependence of \(\Lambda\) as discussed below in Sec. IV A. The values of \(\Delta\) obtained in this way are larger than those obtained from fits to ZF-\(\mu\)SR data, and moreover \(\Delta\) exhibits an increase with increasing \(H_L\) (not shown) if allowed to vary with field. This behavior indicates that the data depart somewhat from the form of Eq. (2), and we consider the fit values of \(\Delta\) and \(\Lambda\) to be of qualitative significance only.

If the exponential damping were due to a (Lorentzian) distribution of static contributions to \(H_\text{loc}\), the observed ZF value of \(\Lambda\) leads to an estimate \(\Delta/\gamma_\mu \sim 1\) Oe for the spread of the local fields \(H_\text{loc}\). Then, an applied longitudinal field of order 10 Oe should nearly decouple \(H_\text{loc}\) and there should be almost no damping. However, it can be seen from Fig. 5 that,

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{Fig4.png}
\caption{(Color online) Representative ZF- and LF-\(\mu\)SR spin polarization decay functions. (a) \(\text{Pr}_{1-x}\text{La}_x\text{Os}_4\text{Sb}_{12}\). Triangles: \(H_L = 5.9\) Oe. Diamonds: \(H_L = 16.1\) Oe. Squares: \(H_L = 121\) Oe. (b) \(\text{Pr(Os}_{0.9}\text{Ru}_{0.1})_4\text{Sb}_{12}\). Triangles: \(H_L = 5.3\) Oe. Diamonds: \(H_L = 16.0\) Oe. \end{figure}
in general, \( \Lambda \) is reduced only slightly for \( H_L = 10 \text{ Oe} \). Thus, the exponential damping is not decoupled, which is evidence that \( \Lambda \) is dynamic rather than static in origin.\(^8\) The observed decoupling in Fig. 4 is associated solely with the behavior of \( G^{\text{KT}}(\Delta, t) \), hence with quasistatic relaxation by Sb nuclear dipolar fields.

For any distribution of quasistatic local fields, the ZF-\( \mu \)-SR asymmetry at long times is expected to approach 1/3 of its initial value \( A \).\(^3\) In Pr-based samples, however, the zero-field value of the asymmetry at long times is typically much lower than \( A/3 \). For PrRu\(_4\)Sb\(_{12}\), this can be seen in Fig. 4(c) (circles) (see also Fig. 2 of Ref. 18). Like the absence of decoupling, this behavior is evidence that the exponential damping is dynamic.

### IV. DISCUSSION

**A. Muon relaxation by fluctuating \(^{141}\text{Pr} \) nuclear spins**

Hayano et al.\(^{3,23} \) calculated the LF-\( \mu \)-SR and TF-\( \mu \)-SR relaxation rates due to dipole-coupled nuclear spins based on the theory of magnetic resonance absorption formulated by Kubo and Tomita.\(^{36} \) In their calculation, spin dynamics arises from muon diffusion in a lattice of quasi-static nuclear spins, but the treatment applies equally to the case where the muon is stationary and it is the nuclear spins that are fluctuating; Lowe and Tse\(^{35} \) carried out an equivalent calculation for relaxation of nuclear spins, with essentially the same result. We therefore apply the results of Hayano et al. to the present experiments, after modification to include hyperfine enhancement of the \(^{141}\text{Pr} \) nuclear spins. This is accomplished by replacing the bare \(^{141}\text{Pr} \) gyromagnetic ratio \( \gamma_{141}\) by the enhanced value \( \gamma_{141}(1+K) \), where \( K \) is the hyperfine-enhancement factor (i.e., the \(^{141}\text{Pr} \) Knight shift),\(^{29,34} \) assumed to be isotropic for the tetrahedral\(^2 \) Pr site. The damping rate \( \Lambda \) is

\[
\Lambda = \frac{\alpha_{\text{VV}}^2}{2} \left[ \frac{3\tau_c}{1 + (\gamma_{\mu}H_L\tau_c)^2 + 1 + [\gamma_{\mu}^{141}\gamma(1+K)]^2H_L^2\tau_c^2} \right] \left( 1 + 6\tau_c \right),
\]

where \( \alpha_{\text{VV}} \) is the high-field muon Van Vleck relaxation rate\(^{23} \) due to \(^{141}\text{Pr} \) dipolar fields (used here as a measure of the rms amplitude of these fields), \( \tau_c \) is the correlation time of the \(^{141}\text{Pr} \) spin fluctuations, and a powder average has been taken. The rapid-fluctuation limit \( \alpha_{\text{VV}}\tau_c < 1 \) is assumed, since otherwise an exponential damping function would not be expected.\(^{23} \) This relation includes the contributions to \( \Lambda \) of both longitudinal \(^{141}\text{Pr} \) spin fluctuations,\(^{35} \) which are assumed to have a common correlation time \( \tau_c \). The field dependence of \( \Lambda \) arises from the fact that the muon spin relaxation rate is proportional to the fluctuation noise power at the muon Zeeman frequency \( \gamma_{\mu}H_L \); for weakly coupled nuclear spins, the dipolar fluctuation spectrum consists of broadened peaks centered at \( 0, \gamma_{\mu}H_L \), and \(-\gamma_{\mu}H_L \),\(^{32,35} \) corresponding to each of the terms of Eq. (3).

From Fig. 5, it can be seen that the field dependence of \( \Lambda \) is generally well fitted by Eq. (3). We find, however, that the form of this relation does not determine \( K \) well compared to the other fitting parameters. We therefore obtain \( K \) independently from the observed low-temperature molar susceptibility \( \chi_{\text{mol}} \) of the Pr ions,\(^{26,27,37} \) and fit it in the fitting. This is done using the relation\(^{29,34,38} \).
\[ K = K_x = a_{\text{hy}} x_{\text{mol}}, \tag{4} \]

where \( a_{\text{hy}} = 187.7 \text{ m} \text{ol} \text{ emu}^{-1} \) is the Pr atomic hyperfine coupling constant. The calculated values of \( K_x \) are given in Table I, together with the experimental values of \( \sigma_{VV} \) and \( \tau_c \) obtained from the fits.

### B. Comparison of data to hyperfine-enhancement model

Next, we compare the experimental values of \( \sigma_{VV} \) and \( \tau_c \) to those expected from the hyperfine-enhancement scenario, assuming dipolar couplings between all spins. We make the ansatz that the \(^{141}\text{Pr}\) spin fluctuations are due to spin-spin interactions within the \(^{141}\text{Pr}\) spin system; in analogy with the discussion of muon spin relaxation in Sec. III A, one would expect significant \(^{141}\text{Pr}\) spin-lattice relaxation by \( 4f \) electronic spin fluctuations to result in considerable temperature dependence of \( \Lambda \) contrary to experiment.

We first calculate the “unenhanced” (i.e., using the bare \(^{141}\text{Pr}\) gyromagnetic ratio) powder-average \( \mu^+ \times \sigma_{VV} \) Van Vleck relaxation rate \( \sigma_{VV}^0 \) from a standard lattice sum\(^{23,32}\) for the candidate \( (0, 1, 0.15, 12) \) muon site\(^8\) (12e in Wyckoff notation) in the filled-skutterudite structure (space group \( I\bar{m}3 \)). For dipolar \(^{141}\text{Pr}-^{141}\text{Pr}\) coupling, the correlation time \( \tau_c^0 \) in the absence of hyperfine enhancement is estimated by the inverse of the unenhanced like-spin \(^{141}\text{Pr}-^{141}\text{Pr}\) Van Vleck rate, which is obtained from a lattice sum similar to that for \( \sigma_{VV}^0 \).\(^{32}\) The hyperfine-enhanced values of these quantities are then\(^{29,34}\)

\[ \sigma_{VV} = \sigma_{VV}^0 (1 + K) \tag{5} \]

and

\[ \tau_c = \tau_c^0 (1 + K)^2. \tag{6} \]

In both cases, the dependence on \( K \) comes solely from the hyperfine enhancement of \( \sigma_{VV} \) (Refs. 29 and 34).

The calculated values of \( \sigma_{VV} \) and \( \tau_c \) are given in Table I. For the La-doped alloys, ensemble averages of the lattice sums have been taken over random \(^{141}\text{Pr}\) site locations.\(^{32}\) The experimental and calculated values of \( \sigma_{VV} \) are in rough agreement, but the experimental values of \( \tau_c \) are systematically smaller than the calculated values, sometimes by more than an order of magnitude. Correspondingly, the inequality \( \sigma_{VV} \tau_c \ll 1 \) required for our analysis is satisfied by the experimental values of \( \sigma_{VV} \) and \( \tau_c \) but usually not by the calculated values.

The discrepancy between experimental and calculated values of \( \tau_c \) is most likely an indication that the assumption of purely dipolar \(^{141}\text{Pr}-^{141}\text{Pr}\) interactions is not valid. Indirect Ruderman-Kittel-Kasuya-Yosida (RKKY)-like interactions mediated by the \( \text{Pr}^3+ \) intraionic exchange interaction\(^{26}\) may decrease \( \tau_c \) considerably, since they are also hyperfine enhanced, but are difficult to estimate in \( \text{PrOs}_4\text{Sb}_{12} \). A brief discussion of limits on the exchange-mediated \(^{141}\text{Pr}-^{141}\text{Pr}\) interaction constant \( J_{ex}^{141} \) is given in the Appendix, which concludes that indirect interactions would account for the experimental values of \( \tau_c \) (Table I) with only a modest \( \text{Pr}^3+ \) exchange coupling.

We note that \( \tau_c \) is also the \(^{141}\text{Pr}\) NMR signal lifetime (spin-echo decay time) \( T_2 \), so that \(^{141}\text{Pr}\) NMR experiments would provide an independent measure of this quantity. Unfortunately, the values of \( \tau_c \) from Table I (\( \approx 1 \mu s \)) are too short for the NMR signal to be observable using current spectrometer technology. Moreover, a search for the \(^{141}\text{Pr}\) resonance would be difficult because of uncertainty in the hyperfine-enhancement factor \( K \). The mere observation of a \(^{141}\text{Pr}\) NMR signal would therefore significantly modify the conclusions of this paper, a fact which might motivate such a search.

An exchange-mediated \(^{141}\text{Pr}-\mu^+ \) interaction, using a Fermi contact interaction between the mediating electrons and the muon, could also be present. A scalar interaction \( \propto \mathbf{I} \cdot \mathbf{S}_\mu \), where \( \mathbf{I} \) and \( \mathbf{S}_\mu \) are \(^{141}\text{Pr}\) nuclear and muon spin operators, respectively, leads to a muon spin relaxation rate of the form of Eq. (3) but only with the second term in brackets.\(^{39}\) Unfortunately, the relative strengths of dipolar and exchange-mediated interactions cannot be determined accurately from fits of an appropriately generalized version of Eq. (3) to the data. Exchange-mediated interactions would, however, be unlikely to dominate (hyperfine-enhanced) \( \mu^+ \times \sigma_{VV} \) dipolar interactions, since in \( f \)-electron metals, the magnitudes of dipolar and electron-mediated interactions between local electronic moments and muon spins are usually comparable.\(^{40}\) The rough agreement between experimental and calculated dipolar values of \( \sigma_{VV} \) (Table I) is consistent with this observation.

Other sources of uncertainty in the comparison between experimental and calculated parameters in Table I include (1) the fact that the low-temperature susceptibility may not be entirely due to the Van Vleck mechanism, leading to error in the calculation of \( K_x \), and (2) the fact that the calculation of \( \sigma_{VV} \) depends on the assumed muon stopping site in \( \text{PrOs}_4\text{Sb}_{12} \). The stopping site has not been determined definitively; indeed, high-field TF-\( \mu \text{SR} \) (Ref. 41) suggests that there may be more than one muon site. Given these caveats, together with the qualitative nature of parameters derived from fitting the \( \mu \text{SR} \) data (Sec. III B), the agreement between the experimental results and the hypothesis of hyperfine-enhanced \(^{141}\text{Pr}\) nuclear magnetism can be regarded as satisfactory.

Figure 6 gives the Ru and La concentration dependencies of the zero-field damping rate \( \Lambda(0) \) just above \( T_c \). We see that \( \Lambda(0) \) decreases as the Pr sublattice is diluted with La ions, as expected if the dynamic relaxation is due to \(^{141}\text{Pr}\) nuclear magnetism. In \( \text{PrOs}_{1-x}\text{Ru}_x\text{Sb}_{12} \), where the Pr sublattice is not diluted, it can be seen in Fig. 6(b) that \( \Lambda(0) \) generally increases by \( \approx 50\% \) as \( x \) is increased from zero and decreases again as \( x \rightarrow 1 \). For dipolar coupling, \( \Lambda(0) \approx 5\tau_c^0 \sigma_{VV} \tau_c \) [cf. Eq. (3)], so that the \( K \) dependencies of \( \sigma_{VV} \) and \( \tau_c \) [Eqs. (5) and (6)] cancel and there should be no dependence of \( \Lambda(0) \) on Ru concentration. However, this cancellation would not necessarily hold for an exchange-mediated interaction, which we have seen is necessary to understand the short experimental values of \( \tau_c \). The Ru concentration dependence is not well understood, but at least two mechanisms may be involved: (1) the concentration dependence of \( \Delta E_{CEF} \), which affects \( x_{\text{mol}} \) and hence \( K_x \) [Eq. (4)], and (2) the (unknown) concentration dependence of \( J_{ex}^{141} \) across the alloy series.
FIG. 6. Concentration dependence of zero-field low-temperature exponential damping rate \( \Lambda(0) \) in (a) \( \text{Pr}_{1-x}\text{La}_x\text{Os}_4\text{Sb}_{12} \) and (b) \( \text{Pr}_x\text{Ru}_{1-x}\text{Os}_4\text{Sb}_{12} \).

V. CONCLUSIONS

ZF- and LF-\( \mu \)SR measurements have been carried out in the filled-skutterudite alloys \( \text{Pr}_{1-x}\text{Ru}_x\text{Os}_4\text{Sb}_{12}, x=0.05, 0.1, 0.2, 0.6, \) and 1.0, and \( \text{Pr}_{1-x}\text{La}_x\text{Os}_4\text{Sb}_{12}, y=0.2, 0.4, 0.6, \) and 0.8, to clarify the origin of the dynamic damping of the muon spin relaxation observed in these alloys. At low temperatures, LF-\( \mu \)SR experiments in both alloy series indicate that static local field distributions and dynamic fluctuations are both involved in muon spin relaxation. The temperature and concentration dependencies of the muon damping rate \( \Lambda \) suggest that it is due to hyperfine-enhanced \( ^{141}\text{Pr} \) nuclear magnetism; the enhancement is responsible for the increased \( ^{141}\text{Pr} \) nuclear spin-spin interaction strength and consequent rapid \( ^{141}\text{Pr} \) spin fluctuations. Further evidence for this picture comes from the field dependence of \( \Lambda \), which is in reasonable agreement with fits to the model of Hayano et al.\(^{23} \) and calculated coupling strengths (Table I) assuming hyperfine enhancement and exchange-mediated spin-spin coupling between \( ^{141}\text{Pr} \) nuclei.

We conclude that hyperfine-enhanced \( ^{141}\text{Pr} \) nuclear spin fluctuations account for the observed exponential damping of the muon spin relaxation function in \( \text{PrOs}_4\text{Sb}_{12} \) and its alloys and that electronic spin fluctuations (other than the \( \text{Pr}^{3+} \) electronic response involved in hyperfine enhancement) are not directly involved in the muon spin relaxation.

ACKNOWLEDGMENTS

We are grateful to D. Arseneau, B. Hitti, S. R. Kreitzman, K. Nagamine, and K. Nishiyama for help during the experiments, to S. K. Kim for help with sample preparation, and to W. G. Clark and C. M. Varma for valuable discussions. This work was supported by the U.S. NSF Grants No. 0102293 and No. 0422674 (Riverside), No. 0203524 and No. 0604015 (Los Angeles), and No. 0335173 (San Diego), the U.S. DOE Contract No. DE-FG-02-04ER46105 (San Diego), and the Grant-in-Aid for Scientific Research Priority Area “Skutterudite” No. 15072206 (Tokyo) of the Ministry of Education, Culture, Sports, Science, and Technology, Japan. One of us (T.Y.) wishes to acknowledge the JSPS Postdoctoral Program for Research Abroad.

APPENDIX: EXCHANGE-MEDIATED \( ^{141}\text{Pr}^{141}\text{Pr} \) SPIN INTERACTION

Consider a \( ^{141}\text{Pr}^{141}\text{Pr} \) spin interaction Hamiltonian of the form

\[
\mathcal{H} = \mathcal{H}_{\text{dip}} + \mathcal{H}_{\text{ex}} = 141\mathcal{J}_{\text{dip}}(3I_1 \cdot r_{12} - I_1 \cdot I_2) + 141\mathcal{J}_{\text{ex}}I_1 \cdot I_2,
\]

where \( 141\mathcal{J}_{\text{dip}} \) and \( 141\mathcal{J}_{\text{ex}} \) are the interaction constants for \( ^{141}\text{Pr}^{141}\text{Pr} \) dipolar and indirect exchange couplings, respectively, and \( r_{12} \) is the distance between \( ^{141}\text{Pr} \) spins \( I_1 \) and \( I_2 \). A scalar exchange interaction has been assumed for simplicity. Both \( 141\mathcal{J}_{\text{dip}} \) and \( 141\mathcal{J}_{\text{ex}} \) are hyperfine enhanced. In a simplified model (singlet ground and excited CEF-split states),\(^{26,42} \) the ratio \( 141\mathcal{J}_{\text{ex}}/141\mathcal{J}_{\text{dip}} \) is approximately given by

\[
141\mathcal{J}_{\text{ex}}/141\mathcal{J}_{\text{dip}} = \mathcal{J}_{\text{ex}}/\mathcal{J}_{\text{dip}},
\]

where \( \mathcal{J}_{\text{ex}} \) and \( \mathcal{J}_{\text{dip}} \) are the corresponding interaction constants for \( \text{Pr}^{3+} \) interionic exchange and dipolar coupling, respectively.

To our knowledge, \( \mathcal{J}_{\text{ex}} \) has not been determined accurately in \( \text{PrOs}_4\text{Sb}_{12} \) or its alloys. Fits to susceptibility data of CEF models using a molecular-field approximation to the exchange coupling\(^{43} \) yield a molecular-field constant \( \lambda \approx 3.9 \text{ mol/emu} \). This gives \( \mathcal{J}_{\text{ex}}/k_B = N_s \mu_B^2 / k_B \gamma_{\text{eff}} = 0.14 \text{ K} \), where the \( T=0 \) Van Vleck effective moment \( \mu_{\text{eff}} = 0.71 \mu_B \) has been assumed\(^1 \) and \( \gamma_{\text{eff}} \) is an effective number of nearest neighbors. This estimate should probably be considered a rough upper bound. It satisfies the criterion\(^{44,45} \)

\[
\mathcal{J}_{\text{ex}}^* \ll \Delta E_{\text{CEF}}
\]

for the absence of exchange-induced magnetic ordering; as noted previously, \( \Delta E_{\text{CEF}}/k_B \approx 7 \text{ K} \). There is no sign of magnetic ordering in \( \text{PrOs}_4\text{Sb}_{12} \), and many of its electronic properties can be accounted for without invoking an exchange interaction.\(^5 \) The dipolar interaction \( \mathcal{J}_{\text{dip}} \) can, however, be calculated: its maximum value is \( \mathcal{J}_{\text{dip}}/k_B = (g \mu_B)^2 / k_B r_{\text{nn}}^3 \approx 8 \times 10^{-3} \text{ K} \), where \( r_{\text{nn}} \) is the nearest-neighbor \( \text{Pr-Pr} \) distance. A value of \( \mathcal{J}_{\text{dip}} \) an order of magnitude larger than this would lead to \( 141\mathcal{J}_{\text{ex}}/141\mathcal{J}_{\text{dip}} \gg 1 \) from Eq. (A2) without violating Eq. (A3) and could account for the experimental values of \( \tau_c \) (Table I).

Our notation for this site, which differs slightly from that of this reference, is consistent with the axis order for the Im$\bar{3}$ group in International Table for Crystallography.

That is, a field that varies slowly compared to the muon time scale of ~10 μs.

μSR measurements on the end compounds LaOs$_4$Sb$_{12}$ and PrRu$_4$Sb$_{12}$ have been previously reported (Refs. 16–18).

The slightly larger value of $\Delta$ in LaOs$_4$Sb$_{12}$ may reflect the contribution of (unenhanced) $^{129}$La nuclear dipolar fields.

A. Amato, Rev. Mod. Phys. 69, 1119 (1997).
