We report results of zero-field muon spin relaxation experiments on the filled-skutterudite superconductors Pr$_{1-x}$Ce$_x$Pt$_4$Ge$_{12}$, $x = 0$, 0.07, 0.1, and 0.2, to investigate the effect of Ce doping on broken time-reversal symmetry (TRS) in the superconducting state. In these alloys broken TRS is signaled by the onset of a spontaneous static local magnetic field $B_s$ below the superconducting transition temperature. We find that $B_s$ decreases linearly with $x$ and $\rightarrow 0$ at $x \approx 0.4$, close to the concentration above which superconductivity is no longer observed. The (Pr,Ce)Pt$_4$Ge$_{12}$ and isostructural (Pr,La)Os$_4$Sb$_{12}$ alloy series both exhibit superconductivity with broken TRS, and in both the decrease of $B_s$ is proportional to the decrease of Pr concentration. This suggests that Pr-Pr intersite interactions are responsible for the broken TRS. The two alloy series differ in that the La-doped alloys are superconducting for all La concentrations, suggesting that in (Pr,Ce)Pt$_4$Ge$_{12}$ pair-breaking by Ce doping suppresses superconductivity. For all $x$ the dynamic muon spin relaxation rate decreases somewhat in the superconducting state. This may be due to Korringa relaxation by conduction electrons, which is reduced by the opening of the superconducting energy gap.

I. INTRODUCTION

The superconducting transition always breaks gauge symmetry, which is the only broken symmetry in “conventional” superconductors. Unconventional superconductivity is characterized by additional broken symmetries, including time-reversal symmetry (TRS) [1,2]. Broken TRS in superconductors, which is quite rare, is especially interesting, because it implies not just unconventional pairing, but also the existence of twofold or higher degeneracy of the superconducting order parameter. The detection of a spontaneous but very small internal field $B_s$ below the superconducting transition temperature $T_c$ in a number of superconductors [3–12] is strong experimental evidence for broken TRS.

Zero-field muon spin relaxation (ZF-μSR) is especially sensitive to small changes in internal fields and can often measure fields of 0.01 mT, corresponding to $10^{-2}$ to $10^{-3}$ $\mu_B$ if produced by dipolar coupling to a lattice of local moments. This makes ZF-μSR an extremely powerful technique for discovering and characterizing TRS breaking in exotic superconductors. Spontaneous fields $B_s$ have been observed by ZF-μSR in the heavy-fermion superconductors (U, Th)Be$_{13}$ [3] and UPt$_3$ [4] (although not without controversy [13,14]; see also [15]), the candidate chiral p-wave superconductor Sr$_2$RuO$_4$ [5], the noncentrosymmetric superconductors LaNi$_2$C$_2$ [6], SrPtAs [7], and Re$_2$Zr [8], the centrosymmetric superconductor LaNi$_4$Ga$_2$ [9], and the filled skutterudite superconductors (Pr,La)Os$_4$Sb$_{12}$ [10,11] and PrPt$_4$Ge$_{12}$ [12].

The ratios of the superconducting gaps to $k_BT_c$ in PrOs$_4$Sb$_{12}$ ($T_c = 1.8$ K) [16] and PrPt$_4$Ge$_{12}$ ($T_c = 7.9$ K) [17] are similar, but their crystalline-electric-field (CEF) level splitting schemes are quite different. Both have the same nonmagnetic singlet $\Gamma_1$ ground state, but in PrOs$_4$Sb$_{12}$ the first excited triplet $\Gamma_4^{(2)}$ CEF-split state (splitting ~8 K) strongly hybridizes with the ground state and conduction electrons [18], generating a heavy-fermion state, whereas in PrPt$_4$Ge$_{12}$ the first excited CEF state is a different triplet ($\Gamma_4^{(1)}$ in $T_h$ notation), and the splitting is much larger (120–130 K) [17,19]. Heavy-fermion behavior is not observed in thermodynamic data for PrPt$_4$Ge$_{12}$ [17].

ZF-μSR measurements in both PrOs$_4$Sb$_{12}$ and PrPt$_4$Sb$_{12}$ are consistent with a superconducting state that breaks TRS [10,12], although to date neither the detailed symmetry of the pairing nor its irreducible representation have been well determined. ZF-μSR experiments in the Pr(Os, Ru)$_4$Sb$_{12}$ and (Pr,La)Os$_4$Sb$_{12}$ alloy series [11,20] suggest that broken TRS is suppressed for Ru concentration $\geq 0.6$ but persists up to La concentration $\approx 1$, and support a crystal-field excitonic Cooper pairing mechanism for TRS-breaking superconductivity [11].

A detailed study of the evolution of the superconducting and normal state properties of (Pr,Ce)Pt$_4$Ge$_{12}$ raises interesting questions about broken TRS in PrPt$_4$Ge$_{12}$ [21]. Superconductivity is suppressed with increasing Ce with positive curvature up to $x = 0.4$, above which no evidence for superconductivity was observed down to 1.1 K. From specific-heat measurements it was shown that the electron correlations are enhanced with increasing Ce concentration. The $C(T)/T$ data in the superconducting state are best described by a $T^3$ dependence for $x = 0$ [21,22] and an $e^{-\Delta/E_F}$ dependence for $x \geq 0.05$ [21], indicating a crossover from a nodal to nodeless superconducting energy gap or the suppression from multiple to single BCS type superconducting...
energy motivated the current investigation on the evolution of broken TRS in PrPt$_4$Ge$_{12}$ with Ce substitution. In this article we report the results of ZF-μSR experiments in Pr$_{1-x}$Ce$_x$Pt$_4$Ge$_{12}$, which were undertaken to study the evolution of the spontaneous local field $B_s$ below $T_c$ with Ce doping. A linear decrease of $B_s$ with Ce concentration is observed up to $x = 0.2$. Our results suggest that $B_s$ is suppressed to zero at $x \approx 0.4$, which is near the critical concentration for suppression of $T_c$ to zero. This resembles the behavior of $B_s$ in (Pr,La)Os$_4$Sb$_{12}$, where broken TRS is associated directly with the Pr concentration, more than in Pr(Os,Ru)$_4$Sb$_{12}$, where the Pr concentration is unchanged [11].

II. EXPERIMENTAL

Powder samples of polycrystalline Pr$_{1-x}$Ce$_x$Pt$_4$Ge$_{12}$ with $x = 0$, 0.07, 0.1, and 0.2 were synthesized as described in Ref. [21]. Rietveld refinements were conducted on powder XRD patterns for each sample. The body-centered-cubic (b) Pr$_0$μ asymmetry, proportional to the $B_s$ evolution of the spontaneous local field $B_s$ in (Pr,La)Os$_4$Sb$_{12}$, where broken TRS is associated directly with the Pr concentration, more than in Pr(Os,Ru)$_4$Sb$_{12}$, where the Pr concentration is unchanged [11].

FIG. 1. (Color online) Time evolution of $\mu^+$ decay positron asymmetry, proportional to the $\mu^+$ spin polarization $P_\mu(t)$, above and below the superconducting transition in (a) PrPt$_4$Ge$_{12}$ and (b) Pr$_{0.9}$Ce$_{0.1}$Pt$_4$Ge$_{12}$. A constant signal from muons that miss the sample and stop in the silver sample holder has been subtracted from the data.
parameter due to lattice defects, impurities, etc. [31,32], depend strongly on the nature and density of such defects [1] (which might explain the difference between our results and those of Ref. [12]). Very rough estimates from the results of [31,32] for the field at an impurity site (which is of course not the muon site) are of the order of 0.01 mT, an order of magnitude smaller than our values of $\Delta_e(0)/\gamma\mu_B$.

A striking difference between (PrO$_5$Sb$_{12}$) and (PrPt$_4$Ge$_{12}$)-based materials is the fact that in the former alloy the observed quasistatic relaxation in the normal state is accounted for by Sb and Sb nuclear dipolar fields [28], whereas in (Pr,Ce)Pt$_4$Ge$_{12}$, the latter, none of the bare (i.e., unenhanced) nuclear magnetic moments are large enough to do this. The largest contribution is from $^{141}$Pr nuclei, for which a simple lattice-sum second moment calculation [27] yields $\Delta_e(\text{bare}) \approx 0.04 \mu s^{-1}$ assuming the $\mu^+$ site reported in Ref. [10].

Comparison with measured values of $\Delta_e$ (Table I) shows that $^{141}$Pr hyperfine enhancement by about 5 is required. The enhancement factor $K$ is given by $K = \frac{\sigma_{\text{HF}}}{\sigma_{\text{bare}}}$ [28,33], where $\sigma_{\text{HF}} = 187.7$ mole/emu is the Pr atomic hyperfine coupling constant. For PrPt$_4$Ge$_{12}$, $X_{\text{nuc}} = 23 \times 10^{-3}$ emu/mole-Pr at low temperatures [12] so that $K \approx 4.3$. This is close to the required value, although uncertainties in the anisotropy of the hyperfine enhancement and the $\mu^+$ site prevent a detailed comparison. We conclude that dipolar fields from hyperfine-enhanced $^{141}$Pr nuclei are responsible for the quasistatic component of the $\mu^+$ spin relaxation in the normal state.

A small dip in $\Delta_e(T)$ is observed just below $T_c^{C_p}$ for $x = 0$, 0.07, and 0.1, as previously reported for PrPt$_4$Ge$_{12}$ [12]. These authors speculated that this might be due to diluted magnetic centers separated by distances of the order of the magnetic penetration depth $\lambda_L = 114(4)$ nm [22], so that $\Delta$ is reduced due to screening of the impurity magnetic field. Such impurities were not observed, however, based on the absence of a low-temperature upturn in the magnetic susceptibilities down to $7\,\text{K}$ [12]. It should also be noted that such screening requires an impurity concentration $c_{\text{imp}} \lesssim 1/\lambda_L^3 \approx 6.8 \times 10^{10} \text{cm}^{-3}$. This concentration is extremely small ($\sim 2 \times 10^{-7}$/Pr ion). The dipolar field at a $\mu^+$ site of the order of this distance from an impurity is $\sim \mu_{\text{imp}}/\lambda_L^3 \approx 6 \times 10^{-10} T/\mu_B$, which is negligible compared to observed values of $\Delta_e/\gamma\mu_B \sim 0.1$ mT from Table I. We conclude that magnetic impurities cannot account for the dip, and its origin remains unknown.

Figure 3 shows the temperature dependence of the relaxation rate $\Delta_e$ in (Pr,Ce)Pt$_4$Ge$_{12}$ obtained by solving Eq. (5). The dependence of $\Delta_e(0)/\gamma\mu_B$ on $x$ is shown in the inset. A linear fit suggests that TRS is suppressed for $x = 0$. This is also the critical Ce concentration for which superconductivity is suppressed [21]. The consequences of this are discussed briefly in Sec. IV.

Figure 4 shows the temperature dependence of the dynamic rate $\Delta_e$ in (Pr,Ce)Os$_8$Ge$_{12}$. There is some indication of a weak temperature dependence of $\Delta$ in the normal state, although the uncertainty is large. Below $T_c$, $\Delta$ decreases with decreasing temperature, most strongly in the end compound PrPt$_4$Ge$_{12}$. We note that $\Delta$ and $\Delta_e$ are anticorrelated in fitting the data to Eq. (3), so that the increased $\Delta$ below $T_c$ could result from a decrease in $\Delta$ (or vice versa). There seems to be some anticorrelation in the neighborhood of $T_c$, particularly for

\[ \Delta_e(T) = \Delta_e(0) \tanh \left[ b \sqrt{\frac{T_c}{T} - 1} \right], \]

where $b$ is a dimensionless coefficient ($b = 1.74$ for an isotropic BCS superconductor in the weak-coupling limit) [29]. The amplitude $\Delta_e(0)$ of $\Delta_e(T)$, $b$, $T_c$, and $\Delta_e$ were varied for best fit. For $x = 0.2$, $\Delta_e(0)$ becomes too small to determine $T_c$ from the fit, and $T_c$ was fixed at $T_c^{C_p}$.\]

The values of the parameters from the fits are shown in Table I. To within error, $b$ is independent of Ce concentration $x$ and smaller than the isotropic BCS value. As shown in Fig. 2, the rise of $\Delta_e(T)$ begins somewhat below $T_c$, so that for $x = 0, 0.07$, and 0.1 $T_c$ is smaller than $T_c^{C_p}$. There is no indication of a phase transition below $T_c^{C_p}$ from bulk measurements [21].

The magnitude of $B_s$ is difficult to estimate theoretically [10]. The uniform spin and orbital fields expected for nonunitary pairing [30] are $\lesssim 10^{-3}$ mT for PrPt$_4$Ge$_{12}$, and therefore negligible compared to $\Delta_e(0)/\gamma\mu_B$ (Table I). Fields produced by inhomogeneity of the superconducting order

FIG. 3. (Color online) Points: Temperature dependence of the relaxation rate \( \Delta \) in (Pr,Ce)Pt\(_4\)Ge\(_{12}\) (circles: \( x = 0 \), squares: \( x = 0.07 \), triangles: \( x = 0.1 \), and diamonds: \( x = 0.2 \)). Curves: Fits of Eq. (6) to the data. Inset: Dependence of the rms width \( \Delta \) (0)/\( \gamma \mu \) of the \( T = 0 \) spontaneous field distribution on Ce concentration \( x \) in Pr\(_{1-x}\)Ce\(_x\)Pt\(_4\)Ge\(_{12}\). Solid line: Linear fit.

\( x = 0 \) (cf. Figs. 2 and 4). However, the asymmetry data exhibit a qualitative increase in relaxation rate below \( T_c \) (Fig. 1), and fits to the data with \( \Lambda \) held fixed (not shown) also yield increases in \( \Delta \).

In both Pr(Os,Ru)\(_4\)Sb\(_{12}\) and (Pr,La)Os\(_4\)Sb\(_{12}\) the exponential damping rate \( \Lambda \) was found to increase slightly with decreasing temperature with no evidence for an anomaly at \( T_c \) [28]. The trend is different in (Pr,Ce)Pt\(_4\)Ge\(_{12}\), where \( \Lambda \) decreases significantly below \( T_c \) (Fig. 4), at least for the lower Ce concentrations (the decrease is smaller for \( x = 0.1 \) and 0.2, making it harder to detect the anomaly).

Hyperfine-enhanced dipolar fields from \(^{141}\)Pr nuclear spin fluctuations were suggested as the origin of the \( \mu^+ \) dynamic relaxation in Pr(Os,Ru)\(_4\)Sb\(_{12}\) and (Pr,La)Os\(_4\)Sb\(_{12}\) [28]. In those materials, nuclear spin dynamics appear to be driven by hyperfine-enhanced nuclear spin-spin interactions that are not strongly affected by superconductivity. Thus the temperature dependence of \( \Lambda \) in (Pr,Ce)Pt\(_4\)Ge\(_{12}\) cannot be accounted for by this mechanism, and in addition the hyperfine enhancement is reduced by two orders of magnitude by the increased Pr\(^{3+}\) CEF splitting in (Pr,Ce)Pt\(_4\)Ge\(_{12}\). Another explanation for the dynamic relaxation and its temperature dependence is necessary.

The decrease of \( \Lambda \) below \( T_c \) might be due to opening of the superconducting gap. The \(^{73}\)Ge nuclear spin-lattice relaxation rate \( 1/\tau_{1e}(T) \), measured using zero-field NQR [34], shows this effect clearly. It is striking that in PrPt\(_4\)Ge\(_{12}\) both \( \Lambda(T) \) [Fig. 4(a)] and \( 1/\tau_{1e}(T) \) [34] exhibit a maximum just below \( T_c \) that resembles the Hebel-Slichter “coherence” peak expected in a superconductor with an isotropic gap [35]. At lower temperatures, however, \( 1/\tau_{1e}(T) \) decreases exponentially [34], whereas \( \Lambda \) remains nonzero down to 25 mK (Fig. 4).

FIG. 4. (Color online) Temperature dependence of the ZF exponential damping rate \( \Lambda \) in Pr\(_{1-x}\)Ce\(_x\)Pt\(_4\)Ge\(_{12}\). (a) \( x = 0 \). (b) \( x = 0.07 \). (c) \( x = 0.1 \). (d) \( x = 0.2 \). Arrows: \( T_{cB} \) from specific-heat measurements [21].

Furthermore, conduction-electron Korringa relaxation is rarely visible in \( \mu \)SR, since the \( \mu^+ \)-conduction-electron hyperfine interaction is weak and the resulting relaxation times are usually much longer than the \( \mu^+ \) lifetime.

Alternatively, dynamic \( \mu^+ \) spin relaxation might arise from fluctuations of \(^{141}\)Pr nuclear dipolar fields due to Korringa relaxation of the Pr nuclei, which is reduced by the opening of the superconducting gap. In Pr(Os,Ru)\(_4\)Sb\(_{12}\) and (Pr,La)Os\(_4\)Sb\(_{12}\) the dynamic muon spin relaxation is provided by fluctuating \(^{141}\)Pr dipolar fields, with quasistatic local fields supplied by Sb nuclei [20,28]. In contrast, in (Pr,Ce)Pt\(_4\)Ge\(_{12}\) the only appreciable nuclear dipolar fields are from \(^{141}\)Pr nuclei. If their fluctuations are rapid the quasistatic field is averaged to zero, leaving a single-exponential \( \mu^+ \) spin relaxation function contrary to experiment (Fig. 1). If on the other hand the \(^{141}\)Pr fluctuations are slow (“adiabatic”), then the \( \mu^+ \) and \(^{141}\)Pr fluctuation rates are nearly the same [27].

In this scenario the opening of the superconducting gap reduces the \(^{141}\)Pr Korringa relaxation rate, which is then mirrored by \( \Lambda \). This is consistent with the data. As noted above, however, the dynamic K-T relaxation function appropriate to this “single-field-source” picture does not fit the data as well as the damped static K-T function of Eq. (3) that assumes two \( \mu^+ \) local field sources: one quasistatic (the hyperfine-enhanced \(^{141}\)Pr dipolar field), and the other fluctuating (the putative conduction-electron hyperfine interaction). Thus it is difficult to decide between these two possibilities, and the mechanism for dynamic \( \mu^+ \) spin relaxation in Pr\(_{1-x}\)Ce\(_x\)Pt\(_4\)Ge\(_{12}\) is not yet fully understood.

**IV. CONCLUSIONS**

ZF-\( \mu \)SR measurements on Pr\(_{1-x}\)Ce\(_x\)Pt\(_4\)Ge\(_{12}\) show that broken TRS in PrPt\(_4\)Ge\(_{12}\) is suppressed by Ce doping. The spontaneous magnetic field that signals broken TRS decreases linearly with \( x \) and \( \rightarrow 0 \) at \( x \approx 0.4 \), which is near the critical concentration for which the superconducting transition temperature is suppressed to zero [21]. In this respect the results resemble those from (Pr,La)Os\(_4\)Sb\(_{12}\), for which the Pr sublattice is also diluted, except that in the latter alloy series the end compound LaOs\(_4\)Sb\(_{12}\) is also superconducting and there is a crossover between superconducting ground states with broken and nonbroken TRS [11].

In (Pr,Ce)Pt\(_4\)Ge\(_{12}\) both broken TRS and superconductivity itself are suppressed above a critical Ce concentration \( x_{cr} \approx 0.4 \). This differs from the situation in (Pr,La)Os\(_4\)Sb\(_{12}\), where the proportionality of \( \Delta_e \) to the Pr concentration indicates that Pr-Pr interactions are responsible for the broken TRS.
in Pr(Os,Ru)4Sb12, where the data suggest that the increase of the CEF excitation energy with Ru concentration is driving the restoration of TRS [11]. The reduction of \( T_c \) in \((\text{Pr},\text{Ce})\text{Pt}_4\text{Ge}_{12}\) appears to be driven by a pair-breaking effect of the Ce doping on the remaining Pr ions, in addition to the weakening of Pr-Pr coupling by dilution.

The reduction of the dynamic \( \mu^+ \) spin relaxation rate \( \Lambda \) below \( T_c \) (Fig. 4) seems to reflect the opening of the superconducting gap. This suggests that conduction electrons contribute to \( \Lambda \) via the Korringa mechanism. Observation of Korringa relaxation in \( \mu^+\text{SR} \) is unusual, and details of the required \( \mu^+ \)-conduction-band interaction remain unclear; more work is required to elucidate this behavior.
